

The heat-shock core moved moderately; the export gate kept only extreme movers

Question: the heat-shock response is induced, so why is almost none of it in the set? Answer: because the gate is a threshold on effect size, not on pathway. WT_heat_up genes sit at median rank percentile 1.4% (median t 10.80) while HSR_core sits at 24.4% (median t 2.05), and the deepest gene the gate admitted sits at 10.21%.

Each point is one gene; ridgelines show density along the same axis. The shaded band is the empirical gate span, 0.0051% to 10.21% (rank 1 to 2,010 of 19,679), and only 213 genes inside it passed, because the gate also required logFC >= 1. The WT_heat_up row is left-shifted by construction and is drawn as the gate's output, not as a result.
